Abstract. Secure mix networks consider the presence of multiple nodes that relay encrypted messages from one node to another in such a way that anonymous communication can be achieved. We consider the Sphinx mix formatting protocol by Danezis and Goldberg (IEEE Security and Privacy 2009), and analyze its use of symmetric-key cryptographic primitives. We scrutinize the reliance on multiple distinct primitives, as well as the use of the ancient LIONESS cipher, and suggest various paths towards improving the security and efficiency of the protocol.

Keywords: Sphinx; mix network; LIONESS; authenticated encryption; sponge

1 Introduction

With the large growth of Internet services, modern users rely more on digital and ubiquitous communications. In this digital domain, privacy needs to be protected against the very nature of the communications, which tend to be easily traceable and produce massive amounts of metadata. Hiding the metadata of communications is hard, but there are some systems, called mix networks, that provide such capabilities. One example is the Sphinx [15] mix network, that is used in privacy protecting applications. The Sphinx mix network format provides security against powerful adversaries and good communications possibilities such as replies, which are not easily available in other mix network formats.

The Sphinx protocol (see Section 2) uses internally many symmetric-key primitives. At first, there is the SHA-2 hash function for hashing. It also includes a HMAC mode [5] to support message authentication. Then, Sphinx uses the LIONESS blockcipher [1], an encryption functionality that is made out of the SEAL stream cipher [31] and a keyed version of the SHA-1 hash function, and evaluates these functions on the message via a Feistel structure. In addition, Sphinx uses a pseudorandom generator to generate entropy for the key. All of these symmetric-key primitives are used in a strongly intertwined manner.

The LIONESS blockcipher is proven to be secure, under the assumption that the underlying primitives SEAL and SHA-1 are sufficiently secure [1], therewith making it particularly useful for Sphinx because of its goal to achieve provable security. However, LIONESS dates back to 1996, and has been outpaced by reality. Attacks on SEAL [17] and SHA-1

result being a free-start collision attack on the full SHA-1, shine a negative light on the security of the LIONESS mode.

1.1 Our Contribution

We suggest to replace the encryption and authentication functionalities by one *authenticated encryption* (AE) functionality. This optimization allows for improved security as the payload now gets authenticated without any efficiency cost. Various existing solutions to AE exist (see Section 1.2), but not all schemes are suitable. In this work, we suggest two approaches for AE that are particularly suited for Sphinx. Both approaches allow for an elimination of many symmetric-key primitive calls, or more formally, for merging these calls into one. This contributes to the simplicity and efficiency of the design.

The first proposal in Section 4 is based on the keyed version of the sponge, which has found recent interest in the design of SHA-3 [10,7]. In more detail, the AE scheme can be seen as an adaption of the full-state SpongeWrap [9,28]. It internally uses a large unkeyed permutation, the state of which is separated into a capacity and a rate. The capacity determines the security bound, and the rate determines the speed at which data is processed. By using a large permutation, one can make a proper balance between the capacity and the rate, and achieve a high level of security. However, the scheme requires nonce respecting behavior: every new evaluation of the AE scheme should be initialized with a unique nonce.

The second proposal in Section 5 is blockcipher based, and is resistant to nonce reuse. The design is somewhat orthogonal to that of conventional nonce reuse resistant AE schemes such as TODO: BART PICK 1-2 best: while other designs consist of a mode built on top of AES, we follow a “tweakable tweakable blockcipher” approach. In other words, we give a powerful construction of a tweakable blockcipher mode on top of a tweakable blockcipher, in such a way that the scheme allows for sufficiently large message and associated data, while still being quite simple and nonce reuse resistant. For a specific instantiation of the construction, we suggest Threefish, a tweakable blockcipher with 1024-bit state by Ferguson et al. used for the Skein hash function family [16]. (Alternative solutions are the use of (i) a large permutation (such as the Keyak [11] or Prøst [25] permutation) in a tweakable Even-Mansour mode [14] and (ii) the TWEAKEY tweakable blockcipher by Jean et al. [21,22,23]. However, the Keyak permutation is known to have an expensive inverse, and the other solutions have a state size which is too small for our purposes.) Threefish has withstood a wide variety of cryptanalysis. TODO: BART PICK 1-2 best

In Section 6, we apply our schemes of Section 4 and Section 5 to the Sphinx format. The new Sphinx format of Figure 4 improves over the earlier one in terms of simplicity, efficiency and security.

1.2 Related Work on Authenticated Encryption

AE enjoys a long and steady line of research, and the ongoing CAESAR competition [13] for the design of new AE schemes has induced renewed attention to the

field. The classical approach to design AE schemes is to build the generic mode of operation on top of a blockcipher (usually AES) in order to process data blocks iteratively TODO: BART pick 1-2A more novel approach is to design AE based on permutations. The most well-known approach is SpongeWrap by Bertoni et al. [9] which got recently generalized by Jovanovic et al. [24] and Mennink et al. [28], and various CAESAR submissions follow this idea. TODO:CITE Only CEASAR competition? Different permutation based approaches include APE [2] and PAEQ [12].

The sponge based proposal in this work follows the literature. Regarding our blockcipher based approach, we have deviated from the state of the art. The reason is that conventional modes often entail overhead and the security level is in the end dominated by what the underlying primitive offers. For blockcipher based modes, using AES internally delivers at most 128-bit security, and often there exist already distinguishability attacks in complexity of about 2^{64} (cf. Bellare et al. [6]). Note that for messages of, say, 1024 bits, a classical AES based mode still requires at least 8 AES evaluations. TODO: CAN THIS REMARK BE LEFT OFF? We remark that also AEZ [20], or more detailed the latest version v4 in the CAESAR competition [19], is also inherently a mode based on 4 and 10 rounds of AES, and has 64-bit security as well. Recent cryptanalysis on AEZ [18,27] has moreover shined a negative light on its security.

2 Sphinx Mix Format

Mix networks rely on mix message formats that provide efficiency and security properties. Sphinx [15] is the most compact cryptographic mix message format, which is provably secure and efficient. Sphinx relies on the *Sphinx blinding logic* technique for generating a session key with nested MAC computations over the public pseudonyms of each predecessor mix. The private key associated to the public key (i.e., pseudonym) is only known by the user, while the session key is used for the encryption of the message. A high-level depiction of Sphinx is given in Figure 1.

Internally, Sphinx uses many cryptographic primitives. First, there are five hash functions, which are used to hash group elements to key bit strings. Then, it uses a pseudorandom generator PRG and a MAC function for the computation of the nested MAC. Finally, an encryption scheme ENC encrypts the payload at every mix.

The hash functions are instantiated using appropriately truncated SHA256 hash functions, and SHA256-HMAC-128 is used as the MAC function. For the encryption, Sphinx relies on the LIONESS blockcipher by Anderson and Biham [1]. This blockcipher is made out of the SEAL stream cipher and a keyed version of the SHA-1 hash function, and evaluates these functions on the message via a Feistel structure. In more detail, denote the stream cipher by S_k and the keyed hash function by H_k . Consider a LIONESS key $k = (k_1, k_2, k_3, k_4)$, where k_1, k_3 will be used to key the stream cipher and k_2, k_4 to key the hash function. To encrypt a message m , LIONESS first splits it into two blocks $m_l \| m_r \leftarrow m$. These blocks

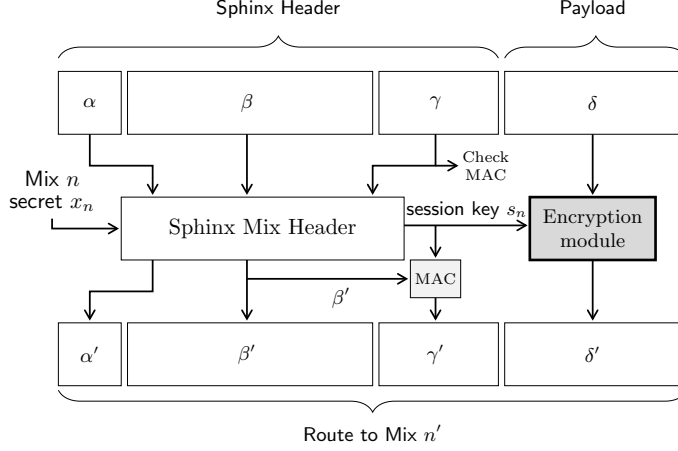

Fig. 1. High-level description of Sphinx [15] to process a Sphinx message $((\alpha, \beta, \gamma), \delta)$ into $((\alpha', \beta', \gamma'), \delta')$ at Mix n with the secret x_n . Key derivation $s_n = \text{keyderive}(\alpha, x_n)$ and the blinding $(\alpha', \beta') = \text{blinding}(\alpha, \beta, \gamma, s_n)$ are omitted from the picture.

are then transformed using a 4-round Feistel structure: $m_r \leftarrow m_r \oplus S_{k_1}(m_l)$, $m_l \leftarrow m_l \oplus H_{k_2}(m_r)$, $m_r \leftarrow m_r \oplus S_{k_3}(m_l)$, $m_l \leftarrow m_l \oplus H_{k_4}(m_r)$. The updated $m_l \| m_r$ constitutes the ciphertext c .

TODO: IS THIS PARAGRAPH NECESSARY? Due to the security parameter choices, the Sphinx construction needs an encryption scheme with a state of at least 1408 bits plus the message length. Based on this, LIONESS appears to be a good option as it has the potential to have a large state and thus act as the permutation required by the Sphinx system. In addition, LIONESS enjoys a security proof if the underlying hash function SHA-1 and stream cipher SEAL are secure [1]. However, the security of LIONESS is undermined by the results mentioned in the introduction.

Besides the doubtful use of LIONESS in the first place, it is noteworthy that Sphinx uses different symmetric-key primitives for various purposes: i.e., SHA-1 is used in LIONESS and SHA-2 for hashing and MACing. These functions are often intertwined, and particularly, three of the cryptographic hash functions are used to transform a secret non-identity group element s to secret keys to the PRG, MAC, and ENC. In other words, denoting these three hash functions as H_{PRG} , H_{MAC} , and H_{ENC} , Sphinx calls the PRG, MAC, and ENC functionalities with $\text{PRG}(H_{\text{PRG}}(s))$, $\text{MAC}(H_{\text{MAC}}(s), m)$ and $\text{ENC}(H_{\text{ENC}}(s), m)$, where s is the secret group element, the secret session key, and m denotes the data to be MACed or ENCd. The synergy between MAC and H_{MAC} is striking, given the designers' choice to instantiate those with SHA256-HMAC-128, and SHA256, respectively. For the case of encryption, the situation is not much clearer, given that LIONESS uses SHA-1 while H_{ENC} is instantiated with SHA256.

Finally, from Figure 1, it becomes apparent that γ is a MAC of β (using session key s), and δ is the encryption of the payload (under session key s). By merging these two functionalities into one *authenticated encryption* scheme that authenticates β and δ and that encrypts δ , one obtains the following improvements:

- Authentication of β and encryption of δ still persists, but authentication of δ is *for free*;
- The session key needs to be processed *only once*;
- There is no need to implement two distinct algorithms.

As such, our main goal in this work is to introduce an AE scheme that suits Sphinx, which will be done in Sections 3-5. The potential employment of the new schemes in Sphinx will be considered in Section 6 in such a way that the remaining above-mentioned issues (such as the redundant usage of cryptographic primitives) are resolved on the fly.

3 Authenticated Encryption

For $n \in \mathbb{N}$, $\{0, 1\}^n$ is the set of n -bit strings, and $\{0, 1\}^{\leq n} = \bigcup_{i=0}^n \{0, 1\}^i$. For two bit strings M, N , their concatenation is denoted by $M \parallel N$ and $M \oplus N$ denotes their bitwise XOR. Furthermore, if $M \in \{0, 1\}^{\leq n-1}$, then $\text{pad}_n(M) = M \parallel 10^{n-1-|M|}$. For a string $N \in \{0, 1\}^n$, we define by $\text{unpad}_n(N)$ the unique string $M \in \{0, 1\}^{\leq n-1}$ such that $\text{pad}_n(M) = N$. For $m \leq n$ and $N \in \{0, 1\}^n$, we denote by $\lceil N \rceil_m$ the leftmost m bits and by $\lfloor N \rfloor_{n-m}$ the rightmost $n-m$ bits of N , in such a way that $N = \lceil N \rceil_m \parallel \lfloor N \rfloor_{n-m}$.

3.1 Definition of Authenticated Encryption

Let $\mu, \nu, \alpha, \tau, \sigma \in \mathbb{N}$ be size values that satisfy $\mu \leq \nu$. Here, μ denotes the size of the message, ν the size of the ciphertext, τ the size of the associated data, and σ the size of the nonce. The value α determines the size of the authentication tag. If no authentication is needed, we have $\alpha = 0$.

An authenticated encryption scheme AE is composed of three algorithms: **KeyGen**, **Enc**, and **Dec**. **KeyGen** is a randomized algorithm that gets as input $\kappa \in \mathbb{N}$ and outputs a random key $key \leftarrow \{0, 1\}^\kappa$. The **Enc** and **Dec** algorithms are defined as follows:

$$\begin{aligned} \text{Enc} : \{0, 1\}^\kappa \times \{0, 1\}^{\leq \mu} \times \{0, 1\}^{\leq \tau} \times \{0, 1\}^\sigma &\rightarrow \{0, 1\}^{\leq \nu} \times \{0, 1\}^\alpha, \\ (key, msg, meta, nonce) &\mapsto (ctxt, auth), \\ \text{Dec} : \{0, 1\}^\kappa \times \{0, 1\}^{\leq \nu} \times \{0, 1\}^\alpha \times \{0, 1\}^{\leq \tau} \times \{0, 1\}^\sigma &\rightarrow \{0, 1\}^{\leq \mu} \cup \{\perp\}, \\ (key, ctxt, auth, meta, nonce) &\mapsto msg / \perp. \end{aligned}$$

Dec outputs the unique msg satisfying $\text{Enc}(key, msg, meta, nonce) = (ctxt, auth)$, or it returns \perp if no such message exists. **Enc** also outputs $meta$ and $nonce$. We allow for a small amount of ciphertext expansion (from μ to ν bits), as long as the encrypted ciphertext $(ctxt, auth, meta, nonce)$ is of size at most λ_{\max} .

3.2 Threat Model

We consider an adversary \mathcal{A} to be any entity attempting to passively access the shared information by monitoring the communication channel, with no incentive to tamper with the content. \mathcal{A} is allowed to generate encryptions under a secret and unknown key. In this case, \mathcal{A} should not learn the encrypted content, beyond that revealed in the associated data.

More technically, adversary \mathcal{A} has query access to \mathbf{Enc} under a secret key key , and it tries to find irregularities among the queries, i.e., some relation that is not likely to hold for a random function. For a function F , let $\mathbf{Func}(F)$ be the set of all functions f with the same interface as F . The advantage of an adversary \mathcal{A} in breaking the secrecy of an authenticated encryption scheme AE is defined as:

$$\mathbf{Adv}_{\mathbf{AE}}^{\text{cpa}}(\mathcal{A}) = \left| \Pr \left(key \xleftarrow{\$} \mathbf{KeyGen}(\kappa) : \mathcal{A}^{\mathbf{Enc}_{key}} = 1 \right) - \Pr \left(\$ \xleftarrow{\$} \mathbf{Func}(\mathbf{Enc}_{key}) : \mathcal{A}^{\$} = 1 \right) \right|.$$

We denote by $\mathbf{Adv}_{\mathbf{AE}}^{\text{cpa}}(Q, T)$ the maximum advantage over all adversaries that make at most Q encryption queries and operate in time T . Depending on the scheme, the adversary \mathcal{A} may be limited to being nonce respecting, so that every query must be made under a different nonce.

For the authenticity of AE, we consider \mathcal{A} to have access to the encryption functionality \mathbf{Enc} under a secret key key , and say that \mathcal{A} *forges* an authentication tag if it manages to output a tuple $(ctxt, auth, meta, nonce) \in \{0, 1\}^{\leq \nu} \times \{0, 1\}^{\alpha} \times \{0, 1\}^{\leq \tau} \times \{0, 1\}^{\sigma}$ such that $\mathbf{Dec}(key, ctxt, auth, meta, nonce) = msg \neq \perp$ and $(msg, meta, nonce)$ was never queried to \mathbf{Enc} before. The forgery attempt may be made under a nonce $nonce$ that has appeared before. The advantage of \mathcal{A} in breaking the authenticity of authenticated encryption scheme AE is defined as:

$$\mathbf{Adv}_{\mathbf{AE}}^{\text{auth}}(\mathcal{A}) = \Pr \left(key \xleftarrow{\$} \mathbf{KeyGen}(\kappa) : \mathcal{A}^{\mathbf{Enc}_{key}} \text{ forges} \right).$$

We denote by $\mathbf{Adv}_{\mathbf{AE}}^{\text{auth}}(Q, R, T)$ the maximum advantage over all adversaries that make at most Q encryption queries, R forgery attempts, and operate in time T .

4 Solution 1: Sponge

The Sponge functions were introduced by Bertoni et al. [10] for cryptographic hashing, but can also be used in a broad spectrum of keyed applications, including message authentication [4, 8, 29, 30] and stream encryption [9, 28]. We will use the keyed sponge in the full-state duplex mode [28], to describe an AE scheme that is suited for the use in Sphinx. As keyed Sponges are merely stream based encryption, a unique nonce is required for every encryption.

The realization of our AE scheme using the sponge is dubbed $\mathbf{AE}^{\pi, \ell, n}$. It is indexed by a permutation π of width b and parameters ℓ and $n \leq b$ which specify the parsing of the message blocks: it considers at most ℓ message blocks

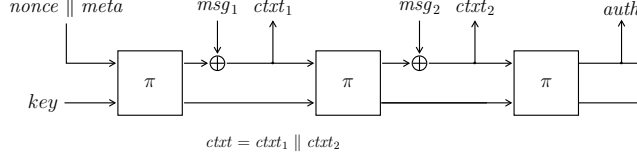

Fig. 2. AE based on a Sponge. Padding of data is excluded from the figure.

Algorithm 1 $\text{Enc}^{\pi, \ell, n}$

Input: $(key, msg, meta, nonce) \in \{0, 1\}^\kappa \times \{0, 1\}^{\leq \mu} \times \{0, 1\}^{\leq \tau} \times \{0, 1\}^\sigma$

Output: $(ctxt, auth) \in \{0, 1\}^{\leq \mu} \times \{0, 1\}^\alpha$

- 1: $\ell' \leftarrow \lceil (|msg| + 1)/n \rceil$
 - 2: $msg_1 || \dots || msg_{\ell'} \xleftarrow{n\text{-blocks}} \text{pad}_{\ell', n}(msg)$
 - 3: $s_0 \leftarrow \text{pad}_n(nonce || meta) || 0^{b-n-|key|} || key$
 - 4: **for** $i = 1, \dots, \ell'$ **do**
 - 5: $s_i \leftarrow \pi(s_{i-1})$
 - 6: $s_i \leftarrow s_i \oplus (msg_i || 0^*)$
 - 7: $ctxt_i \leftarrow \lceil s_i \rceil_n$
 - 8: $s_{\ell'+1} \leftarrow \pi(s_{\ell'})$
 - 9: **return** $(\lceil ctxt_1 || \dots || ctxt_{\ell'} \rceil_{|msg|}, \lceil s_{\ell'+1} \rceil_\alpha)$
-

of n bits. The parameter ℓ can be arbitrarily large, but it is used to show how the length affects the security bound. $\text{AE}^{\pi, \ell, n}$ operates on keys of size $\kappa \leq b - n$ bits, messages and ciphertexts can be of length at most $\mu = \ell \cdot n - 1$ (note that the scheme does not use ciphertext expansion, hence $\mu = \nu$), and the sizes of the associated data and nonce should satisfy $\sigma + \tau \leq n - 1$. The size of the authentication tag is $\alpha \leq n$ (this bound is for simplicity, the scheme generalizes to $\alpha > n$). $\text{AE}^{\pi, \ell, n}$ is depicted in Figure 2. The formal encryption and decryption functionalities are given in Algorithms 1 and 2.

4.1 Security

$\text{AE}^{\pi, \ell, n}$ is a full-state duplex construction [28], but it is easier to explain the security of the construction in terms of the Inner-Keyed Sponge (IKS) of Andreeva et al. [4]. This construction gets as input a key k , an arbitrarily sized message m , and a natural number ρ , and it outputs a digest z of size ρ . That is $\text{IKS}^\pi(k, m, \rho) = z \in \{0, 1\}^\rho$. It is defined as the classical Sponge with an outer part of size n and an inner part of size $b - n$, and with the capacity part being initialized using the key. We consider a specific case of IKS where $\rho \leq n$, which means that the squeezing part of the Sponge takes exactly one round.

The security of variable-input-length $\text{IKS} : \mathcal{K} \times \{0, 1\}^* \rightarrow \{0, 1\}^n$ based on a permutation π is slightly different from the CPA security of Section 3; first, IKS is variable length, so it is compared with a random oracle $\mathcal{RO} : \{0, 1\}^* \rightarrow \{0, 1\}^n$, and second, it is based on an underlying idealized permutation π and the adversary has two-sided oracle access to π . Denote by $\text{Perm}(\{0, 1\}^b)$ the

Algorithm 2 $\text{Dec}^{\pi, \ell, n}$

Input: $(key, ctxt, auth, meta, nonce) \in \{0, 1\}^\kappa \times \{0, 1\}^{\leq \mu} \times \{0, 1\}^\alpha \times \{0, 1\}^{\leq \tau} \times \{0, 1\}^\sigma$

Output: $msg \in \{0, 1\}^{\leq \mu}$ or \perp

```
1:  $\ell' \leftarrow \lceil (|ctxt| + 1)/n \rceil$ 
2:  $ctxt_1 \parallel \dots \parallel ctxt_{\ell'} \xleftarrow{n\text{-blocks}} \text{pad}_{\ell', n}(ctxt)$ 
3:  $s_0 \leftarrow \text{pad}_n(nonce \parallel meta) \parallel 0^{b-n-|key|} \parallel key$ 
4: for  $i = 1, \dots, \ell' - 1$  do
5:    $s_i \leftarrow \pi(s_{i-1})$ 
6:    $msg_i \leftarrow \lceil s_i \rceil_n \oplus ctxt_i$ 
7:   if  $i < \ell'$  then
8:      $s_i \leftarrow ctxt_i \parallel \lfloor s_i \rfloor_{b-n}$ 
9:   else
10:     $s_i \leftarrow \lceil ctxt_i \rceil_{|ctxt| \bmod n} \parallel \lfloor s_i \rfloor_{b-(|ctxt| \bmod n)}$ 
11:  $msg \leftarrow \lceil msg_1 \rceil \parallel \dots \parallel msg_{\ell'} \rceil_{|ctxt|}$ 
12:  $s_{\ell'+1} \leftarrow \pi(s_{\ell'})$ 
13: return  $\lceil s_{\ell'+1} \rceil_\alpha = auth ? msg : \perp$ 
```

set of b -bit permutations. Abusing notation, we refer to the security of IKS against an adversary that has access to either (IKS, π^\pm) or (\mathcal{RO}, π^\pm) , where $k \xleftarrow{\$} \mathcal{K}$, $\pi \xleftarrow{\$} \text{Perm}(\{0, 1\}^b)$, and \mathcal{RO} is a random oracle, by $\text{Adv}_{\text{IKS}}^{\text{cpa}}(\mathcal{A})$. We define by $\text{Adv}_{\text{IKS}}^{\text{cpa}}(Q, S)$ the maximum advantage over all adversaries with total complexity Q , that make at most S primitive queries to π^\pm . The total complexity Q counts the number of *fresh calls* to π if \mathcal{A} were conversing with IKS.

If no authentication is needed, then $\text{Enc}^{\pi, \ell, n}$ and $\text{Dec}^{\pi, \ell, n}$ do not require the computation of $s_{\ell'+1} \leftarrow \pi(s_{\ell'})$ at the end, which saves a permutation call. Related to this, we define ℓ_α as ℓ , if $\alpha = 0$, and $\ell + 1$ otherwise.

Theorem 1. Assume $\pi \xleftarrow{\$} \text{Perm}(\{0, 1\}^b)$ is an ideal permutation. We have

$$\begin{aligned} \text{Adv}_{\text{AE}^{\pi, \ell, n}}^{\text{cpa}}(Q, T) &\leq \frac{(\ell_a Q)^2}{2^{b-n}} + \frac{\ell_a Q S}{2^\kappa}, \\ \text{Adv}_{\text{AE}^{\pi, \ell, n}}^{\text{auth}}(Q, R, T) &\leq \frac{(\ell_a Q)^2}{2^{b-n}} + \frac{\ell_a Q S}{2^\kappa} + \frac{R}{2^\alpha}. \end{aligned}$$

where S is the maximal number of evaluations of π that can be made in time T . The adversaries are required to be nonce respecting.

5 Solution 2: Tweakable Blockcipher Based

The second approach is to apply a large tweakable blockcipher. A tweakable blockcipher $\tilde{E} : \mathcal{K} \times \mathcal{T} \times \mathcal{M} \rightarrow \mathcal{M}$ takes as input a key $k \in \mathcal{K}$, a tweak $t \in \mathcal{T}$, and a message $m \in \mathcal{M}$, and outputs a ciphertext $c \in \mathcal{M}$. It is a permutation for every choice of (k, t) .

For our AE functionality AE, we need a tweakable blockcipher with a large state \mathcal{M} . We suggest using *Threefish*, a tweakable blockcipher by Ferguson et

Algorithm 3 $\text{Enc}^{\text{LRW}[\text{3fish}]}$

Input: $(key, msg, meta, nonce) \in \{0, 1\}^\kappa \times \{0, 1\}^{\leq \mu} \times \text{bint} \times \{0, 1\}^\sigma$

Output: $(ctxt, auth) \in \{0, 1\}^\nu \times \{0, 1\}^\alpha$

1: $c \leftarrow \text{LRW}[\text{3fish}](key, \text{pad}_{1024}(meta), \text{pad}_{128}(nonce), \text{pad}_{1024}(msg))$

2: **return** $(\lceil c \rceil_\nu, \lfloor c \rfloor_\alpha)$

Algorithm 4 $\text{Dec}^{\text{LRW}[\text{3fish}]}$

Input: $(key, ctxt, auth, meta, nonce) \in \{0, 1\}^\kappa \times \{0, 1\}^\nu \times \{0, 1\}^\alpha \times \{0, 1\}^{\leq \tau} \times \{0, 1\}^\sigma$

Output: $msg \in \{0, 1\}^{\leq \mu}$ or \perp

1: $m \leftarrow \text{LRW}[\text{3fish}]^{-1}(key, \text{pad}_{1024}(meta), \text{pad}_{128}(nonce), ctxt \| auth)$

2: $msg \leftarrow \text{unpad}_{\mu+1}(\lceil m \rceil_{\mu+1})$

3: **return** $\lfloor m \rfloor_\alpha = 0 ? msg : \perp$

al. used for the Skein hash function family [16]. Threefish supports block sizes of 256, 512, and 1024 bits. The key size equals the block size, and the tweak size is 128 bits. We focus on the largest variant, Threefish-1024, which for readability we simply denote 3fish:

$$\begin{aligned} \text{3fish} : \{0, 1\}^{1024} \times \{0, 1\}^{128} \times \{0, 1\}^{1024} &\rightarrow \{0, 1\}^{1024}, \\ (k, t, m) &\mapsto c. \end{aligned}$$

3fish can be used for AE directly, i.e., by placing the associated data and nonce into the tweak, and encrypting based on the secret key and this tweak. While the state size of 3fish is reasonably large enough, the tag size is not. One way to resolve this is to employ a random oracle that maps the associated data and nonce to a string of size 128 bits, but this would degrade the security of the construction as forgeries can be found in a complexity 2^{64} . Another way to enlarge the tweak space without adjusting the cipher itself is by using it in a tweakable mode of operation.

Liskov et al. [26] introduced two tweakable modes of operation: while these constructions are originally designed to add a tweak input to a blockcipher, they can equally well be applied to tweakable blockciphers themselves to enlarge the tweak space. We will consider one of these constructions, which makes two evaluations of the underlying cipher:³

$$\begin{aligned} \text{LRW}[\text{3fish}] : \{0, 1\}^{1024} \times \{0, 1\}^{1024} \times \{0, 1\}^{128} \times \{0, 1\}^{1024} &\rightarrow \{0, 1\}^{1024}, \\ (k, t, t', m) &\mapsto \text{3fish}(k, t', \text{3fish}(k, t', m) \oplus t). \end{aligned}$$

This construction can be used to realize $\text{AE}^{\text{LRW}[\text{3fish}]}$ as illustrated in Figure 3 and described in Algorithms 3 and 4. It operates on keys of size $\kappa = 1024$ bits, messages can be of arbitrary length but of size at most $\mu = 1023 - \alpha$, the nonce

³ The other construction is less relevant as it requires an additional key and needs a universal hash function with a 1024-bit range (or smaller, in which case the security of the construction degrades).

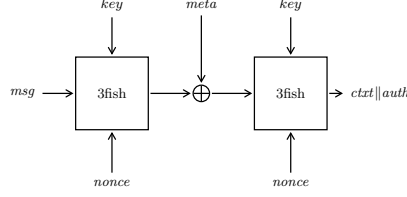

Fig. 3. AE based on LRW[3fish]. Padding of data is excluded from the figure

should be of size $\sigma \leq 127$, and the associated data should be of size at most $\tau \leq 1023$. The ciphertexts are of size *exactly* $\nu = 1024 - \alpha$ bits, where α is the size of the authentication tag. The latter is required to make decryption possible.

5.1 Security

We state the security of $\text{AE}^{\text{LRW}[3\text{fish}]}$ under the assumption that 3fish is a secure tweakable blockcipher. The security of a tweakable blockcipher $\tilde{E} : \mathcal{K} \times \mathcal{T} \times \mathcal{M} \rightarrow \mathcal{M}$ is captured by an adversary \mathcal{A} that has adaptive two-sided oracle access to either \tilde{E}_k for some secret key $k \xleftarrow{\$} \mathcal{K}$, or ideal tweakable permutation $\tilde{\pi}$ with tweak space \mathcal{T} and message space \mathcal{M} , and tries to distinguish both worlds. Denote by $\widetilde{\text{Perm}}(\mathcal{T}, \mathcal{M})$ the set of tweakable permutations. We define the strong PRP security of \tilde{E} as

$$\text{Adv}_{\tilde{E}}^{\text{sprp}}(\mathcal{A}) = \left| \Pr \left(k \xleftarrow{\$} \mathcal{K} : \mathcal{A}^{\tilde{E}_k^{\pm}} = 1 \right) - \Pr \left(\tilde{\pi} \xleftarrow{\$} \widetilde{\text{Perm}}(\mathcal{T}, \mathcal{M}) : \mathcal{A}^{\tilde{\pi}^{\pm}} = 1 \right) \right|.$$

By $\text{Adv}_{\tilde{E}}^{\text{sprp}}(Q, T)$ we denote the maximum security advantage of any adversary \mathcal{A} that makes Q queries and runs in time T .

The security of $\text{AE}^{\text{LRW}[3\text{fish}]}$ follows from a result from [26] on the security of LRW.

Theorem 2. *Let $n = 1024$ be the state size of 3fish. We have*

$$\begin{aligned} \text{Adv}_{\text{AE}^{\text{LRW}[3\text{fish}]}}^{\text{cpa}}(Q, T) &\leq \Theta \left(\frac{Q^2}{2^n} \right) + \text{Adv}_{3\text{fish}}^{\text{sprp}}(2Q, T'), \\ \text{Adv}_{\text{AE}^{\text{LRW}[3\text{fish}]}}^{\text{auth}}(Q, R, T) &\leq \Theta \left(\frac{(Q+R)^2}{2^n} \right) + \text{Adv}_{3\text{fish}}^{\text{sprp}}(2(Q+R), T') + \frac{R2^{n-\alpha}}{2^n - Q}, \end{aligned}$$

where $T' \approx T$. The adversaries may be nonce reusing.

Note that the construction is even secure under *release of unverified plaintext*, where msg is disclosed before tag verification is done [3]. If one considers *nonce respecting* adversaries, the term $\binom{Q}{2}/2^n$ in the analysis of secrecy disappears, and $\frac{R2^{n-\alpha}}{2^n - Q}$ can be replaced with $\frac{R2^{n-\alpha}}{2^n - 1}$.

6 Improving the Sphinx

A naive solution to the state of affairs for Sphinx (Section 2) would be to replace SEAL by a more modern stream cipher and to replace SHA-1 by SHA-3, but there is little point in doing so: versatility of Sponges in general and SHA-3 in particular enables encryption using SHA-3 on the fly; putting a four-round Feistel construction on top of it is overkill. Instead, it makes more sense to simply *replace* LIONESS by a keyed version of the SHA-3. The construction of Section 4 is particularly suited for this purpose, as it is an AE scheme based on the SHA-3 permutation. As the construction offers AE, it can also be used to replace the MAC. In other words, where the original Sphinx MACs β into authentication tag γ and encrypts the payload into δ (both using secret session key s), the construction of Section 4 neatly merges those into

$$(\delta, \gamma) = \text{AE}(s, \text{payload}, \beta), \quad (1)$$

where, for the sake of simplicity, β now represents the associated data and the nonce. We have henceforth obtained the security and efficiency improvement promised in Section 2.

It seems logical to also replace the remaining cryptographic functionalities in Sphinx by SHA-3. However, a second thought reveals that there is little point in doing so: first hashing a key through SHA-3 and then considering the keyed version of the SHA-3 based on this key is less efficient *and* less secure than considering the keyed version of the SHA-3 based on the original key. Therefore, it suffices to have a simple mapping that transforms the secret session key into a bit string.

The downside of the SHA-3 based approach is that the AE scheme of Section 4 does not offer security against nonce reusing adversaries, and in the solution of (1), β represents the associated data as well as the nonce. In Sphinx, the β values are generated using the PRG, and henceforth random, but collisions may appear. Alternatively, one can use the Threefish based mode of Section 5, and use the Skein hash function family [16] to serve for hashing, as it already uses Threefish natively.

Either approach makes the encryption functionality of Sphinx more secure and more efficient. Figure 4 depicts our proposal of using AE in Sphinx. Our AE solutions support associated data as input which could be used for the processing of the header, it natively allows for authentication, and could potentially be used as MAC function. These advantages could be used to integrate part of the nested MAC functionality of Sphinx within the AE. Using our AE schemes in Sphinx *additionally* authenticates the payload for free.
